Abstract

Domain wall networks on the surface of a soliton are studied in a simple theory. It consists of two complex scalar fields, in (3+1)-dimensions, with a global $U(1) \times \mathbb{Z}_n$ symmetry, where $n > 2$. Solutions are computed numerically in which one of the fields forms a Q-ball and the other field forms a network of domain walls localized on the surface of the Q-ball. Examples are presented in which the domain walls lie along the edges of a spherical polyhedron, forming junctions at its vertices. It is explained why only a small restricted class of polyhedra can arise as domain wall networks.

1 Introduction

Any theory with multiple isolated vacua supports domain walls that separate spatial regions containing different vacua. Indeed domain walls arise in a number of diverse areas of particle physics, cosmology and condensed matter physics. Recently, there has been a renewed interest in the study of domain walls due to their appearance in supersymmetric QCD [9] and their relation to D-branes [17]. More generally, interesting analogies between domain walls and D-branes have been observed, with the interactions between domain walls providing insight into more complicated D-brane systems [10]. This provides further motivation for the study of configurations with multiple domain walls, containing junctions and networks.

Domain wall junctions exist in theories with three or more vacua and can be combined to form a planar network [11, 7, 15, 3, 4]. It has been suggested in refs.[5, 6] that a three-dimensional network of domain walls might exist in which a spherical domain wall is a host for a planar network confined to its surface, with the spherical domain wall being stabilized by a fermi gas pressure, as in soliton stars [14]. According to refs.[5, 6] such networks could then form configurations resembling the Platonic solids and fullerene polyhedra, such as the truncated icosahedron of the buckyball. In this paper we explore these ideas, using a simple theory in which a domain wall network is trapped on the surface of a Q-ball. We compute numerical solutions of the theory, presenting explicit examples where a network of domain walls lies along the edges of a spherical polyhedron, forming junctions at its vertices. However, only a small restricted class of polyhedra can arise in this way, as we explain using several examples. Only two of the five Platonic solids (the cube and octahedron) can be realized and no fullerene polyhedra can be obtained. The argument which rules out most polyhedra is based on an examination of the compatibility conditions which arise when assigning vacua to the faces of the polyhedron, and its implications for the distribution of domain wall tensions, which are required to be in equilibrium. The analysis does not depend on the type of soliton on which the domain walls are trapped, and so applies generally to networks on Q-balls, spherical domain walls, soliton stars, monopoles, Skyrmions etc.

2 A Model with Q-balls and Walls

We consider a theory, in (3+1)-dimensions, with two complex scalar fields ψ, ϕ and Lagrangian density

$$\mathcal{L} = \frac{1}{2}\partial_\mu\psi\partial^\mu\bar{\psi} + \frac{1}{2}\partial_\mu\phi\partial^\mu\bar{\phi} - |\psi|^2\left(1 + (1 - |\psi|^2)^2\right) - \beta^2\left|(1 - |\psi|^2)4|\psi|^2 - \phi^n/v^n\right|^2 \quad (2.1)$$

where β and v are real positive parameters and $n > 2$ is an integer. There is a global $U(1) \times \mathbb{Z}_n$ symmetry, corresponding to the transformations $\psi \mapsto e^{i\alpha}\psi$ and $\phi \mapsto \omega_n\phi$ where α is an arbitrary real parameter and $\omega_n = e^{2\pi i/n}$. There is a conserved Noether charge

associated with the $U(1)$ symmetry, given by

$$Q = \frac{1}{2i} \int (\bar{\psi} \partial_t \psi - \psi \partial_t \bar{\psi}) d^3x \quad (2.2)$$

and this allows the possibility of Q-ball solitons [8].

The particular model (2.1) is chosen as one of the simplest examples supporting both solitons and domain walls, as we now explain in detail, but there are many other theories which share these properties, with various kinds of solitons playing host to the walls.

The field equations which follow from (2.1) have $\phi = 0$ as a solution, so a consistent way to find a family of solutions is to consider this reduction directly in the Lagrangian density, to obtain the reduced expression

$$\mathcal{L}_0 = \frac{1}{2} \partial_\mu \psi \partial^\mu \bar{\psi} - U(|\psi|) \quad (2.3)$$

where the potential function is given by

$$U(f) = f^2(1 + (1 - f^2)^2) + 16\beta^2 f^4(1 - f^2)^2. \quad (2.4)$$

If $\beta = 0$ then this is precisely the model in which Q-balls are studied in ref.[2], to which we refer the reader for further details. For small values of β ie. $\beta^2 \ll 1$, the final term in (2.4) may be treated as a small perturbation of the $\beta = 0$ theory, and the Q-ball solutions will be almost unchanged.

A stationary Q-ball has the form

$$\psi = e^{i\nu t} f(r), \quad (2.5)$$

where $f(r)$ is a real radial profile function which satisfies the ordinary differential equation

$$\frac{d^2 f}{dr^2} = -\frac{2}{r} \frac{df}{dr} - \nu^2 f + U'(f), \quad (2.6)$$

with the boundary conditions that $f(\infty) = 0$ and $\frac{df}{dr}(0) = 0$.

This equation can be interpreted as describing the motion of a point particle moving with friction in a potential $U_{\text{eff}}(f) = \nu^2 f^2/2 - U(f)$. This leads to constraints [8] on the potential $U(f)$ and the frequency ν in order for a Q-ball solution to exist. Firstly, the effective mass of f must be negative. Defining $U''(0) = \nu_+^2 > 0$, then this implies that $\nu < \nu_+$. For the potential (2.4) we have that $\nu_+ = 2$, independent of β . Next the minimum of $U(f)/f^2$ must be attained at some positive value of f , say $0 < f_0 < \infty$, and existence of the solution requires that $\nu > \nu_-$ where

$$\nu_-^2 = 2U(f_0)/f_0^2. \quad (2.7)$$

For the potential (2.4) the minimum of $U(f)/f^2$ occurs at $f = f_0 = 1$, and this yields the value $\nu_-^2 = 2U(f_0)/f_0^2 = 2$, again independent of β . Hence, Q-ball solutions exist for the

Figure 1: The Q-ball profile function $f(r)$ for $\nu = 1.5$ with $\beta = 0$ (solid curve) and $\beta = 0.1$ (dashed curve).

range $\sqrt{2} < \nu < 2$. In this paper we are concerned with large Q-balls, that is, $Q \gg 1$, which corresponds to a frequency approaching the lower limit $\nu_- = \sqrt{2}$. Such large Q-balls are well described by the thin wall limit, where the profile function can be approximated by a smoothed-out step function, with $f \approx 1$ inside the Q-ball and $f \approx 0$ outside, with a fairly sharp transition at the surface of the Q-ball. This is demonstrated in fig. 1 where we plot the profile function $f(r)$ (solid curve) for the parameter values $\nu = 1.5$ and $\beta = 0$. This profile function was obtained by solving equation (2.6) numerically using a shooting method. Also displayed in fig. 1 is the profile function (dashed curve) for the parameter values $\nu = 1.5$ and $\beta = 0.1$. This demonstrates that the shape of the Q-ball profile function is not very sensitive to the value of β . The Noether charge (2.2) is slightly larger for $\beta = 0.1$ compared to $\beta = 0$, and in fact the main consequence of a non-zero value of β is a slight modification to the relationship between the charge Q and the frequency ν .

Let us now turn our attention to solutions in which ϕ also has a non-trivial spatial dependence. The form of the Lagrangian (2.1) implies that for sufficiently small β , ie. $\beta^2 \ll 1$, the final term in (2.1) will have a negligible effect on the Q-ball solution and can be ignored. As we have seen in fig. 1 the value $\beta = 0.1$ is within this regime, so we shall make this choice from now on. In fact, one expects that the effect of the final term in (2.1) will be even less for a non-trivial ϕ field than in the case where $\phi = 0$, since the additional contribution drives the ϕ field to minimize this term.

For simplicity we can therefore ignore the deformation of the Q-ball and consider the ϕ field in the background of a fixed Q-ball solution. Since we are interested in static solutions

for ϕ this reduces to studying the theory defined by the energy density

$$\mathcal{E} = \frac{1}{2} \partial_i \phi \partial_i \bar{\phi} + \beta^2 |4f^2(1 - f^2) - \phi^n/v^n|^2 \quad (2.8)$$

where the index i runs over the three spatial coordinates and $f(r)$ is a fixed Q-ball profile function. We shall choose the Q-ball with $\nu = 1.5$, so that $f(r)$ is the solid curve plotted in fig. 1.

The expression $4f^2(1 - f^2)$ is close to zero everywhere except near the surface of the Q-ball, taking its maximal value 1, on the surface $f = \frac{1}{\sqrt{2}}$. From fig. 1 we see that this surface is a sphere of radius $r = r_* \approx 6$. Far from the surface of the Q-ball we will therefore find that $\phi \approx 0$. However, on the surface of the Q-ball the theory will resemble the Wess-Zumino model

$$\mathcal{E}_{\text{WZ}} = \frac{1}{2} \partial_i \phi \partial_i \bar{\phi} + \beta^2 |1 - \phi^n/v^n|^2 \quad (2.9)$$

where, for the moment, we ignore the curvature of the sphere and regard this energy as defining a two-dimensional theory in the plane.

The theory (2.9) is the one studied in refs.[11, 7, 15] where BPS junctions are investigated together with almost-BPS tilings of the plane. We recall the salient features briefly. The theory has n vacua, with ϕ proportional to the n th roots of unity, ie. $\phi = v\omega_n^j$, where $j = 1, \dots, n$. In the following, for brevity, we shall sometimes refer to a vacuum by its label j . There are $n(n - 1)/2$ different species of domain walls, each one connecting any two distinct vacua, say j and k , with a tension (energy per unit length) given by

$$T = 2^{3/2} \frac{n\beta v}{n + 1} |\omega_n^j - \omega_n^k|. \quad (2.10)$$

Thus the tension of a domain wall is proportional to the distance in ϕ space between the two vacua it interpolates between. These domain walls have a width of order v/β and are BPS (they satisfy a first order equation which implies the second order field equation). For $n > 2$, there are also BPS domain wall junctions in which three or more domain walls meet at a point, dividing the plane into sectors with a different vacuum occurring in each sector. The plane can be tiled by almost-BPS junctions, in the sense that each junction is locally close to a BPS junction, but the particular BPS equation varies at different junctions and some junctions are required to be anti-BPS, in that the orientation of the junction is reversed.

Returning now to the three-dimensional model defined by the energy (2.8) the above discussion suggests that there may be solutions in which domain wall junctions form a spherical tiling of the surface of the Q-ball. These domain walls are fully three-dimensional, in that although they are localized close to the Q-ball's surface, they also have a thickness. Such domain wall networks will certainly not be BPS, and effects such as the curvature of the sphere will play an important role, but the tension formula (2.10), and other aspects of planar domain wall junctions, will prove a useful guide in understanding the results obtained.

3 Domain Wall Networks

In this section we describe the results of numerical computations to compute static domain wall networks on the surface of a Q-ball. Motivated by the suggestions in refs.[5, 6] we shall concentrate mainly on investigating examples where the domain walls lie along the edges of a spherical polyhedron, forming junctions at its vertices.

To compute solutions of the static field equations for ϕ , which follow from the variation of the energy defined by (2.8), we solve the associated gradient flow equations, $\frac{\partial \phi}{\partial \tau} = -\frac{\delta \mathcal{E}}{\delta \phi}$, where τ is an artificial time. Spatial derivatives are approximated by second order finite differences and we use a grid containing 101^3 points with a lattice spacing $\delta x = 0.2$. As discussed above, the Q-ball surface has a radius $r_* \approx 6$ and the walls have a width of order v/β . To make the width of the walls of order one, which is a reasonable fraction of the diameter of the sphere, we choose $v = \beta$, where $\beta = 0.1$ as before.

The simplest domain wall network consists of just two junctions, located at antipodal points on the sphere. For the theory with n vacua we may take n equally spaced walls, lying along geodesic arcs joining the two junctions. The domains are equal area segments of the sphere and each vacuum is attained only in one segment, with neighbouring segments containing neighbouring vacua, so that all walls have minimal tension. For later reference, we refer to such a solution as an n -segment network.

It is a simple task to create initial conditions which will yield an n -segment network. ϕ is taken to be the vacuum j , where $1 \leq j \leq n$, at the points which satisfy all the following conditions; (i) $|x_3| < r_* - \mu_1$, (ii) $|r - r_*| < \mu_2$, (iii) $2\pi(j-1)/n + \mu_3 < \varphi < 2\pi j/n - \mu_3$, where r, θ, φ are spherical polar coordinates. At points which do not satisfy all these conditions then $\phi = 0$. The values $\mu_1 = 1, \mu_2 = 2, \mu_3 = 0.1$ were used, though others yield the same results. Condition (i) removes patches around the north and south poles, which is where the junctions will form. Condition (ii) seeds a condensate for ϕ only around the surface of the Q-ball. Condition (iii) sets the correct ordering of vacua, leaving a small buffer between the segments for the domain walls to form. In fig. 2 we display a surface of constant energy density for the solution obtained from the above initial conditions in the simplest case of $n = 3$. The three curved domain walls are clearly evident as the geodesic arcs, and the 3-wall junctions can be seen at antipodal points on the sphere.

Figure 2: Energy density isosurface for the 3-segment network.

Similar solutions have been computed for other values of n .

An important point to clarify is the symmetry of an n -segment network. The energy density has the point group symmetry D_{nh} , but of course the fields themselves do not have this symmetry, since different vacuum values are attained in each of the n segments. In theories with a global symmetry, in this case a discrete $\mathbb{Z}_n$ symmetry, the notion of a field configuration having a spatial symmetry is usually understood to mean that the field configuration obtained after acting with the spatial transformation is equivalent to the original field configuration upto the action of the global symmetry group. In particular this implies that the energy density is strictly invariant. However, the n -segment network is not D_{nh} symmetric in this sense, even though the energy density is. The easiest way to see this is to note that the junction at the north pole has the opposite orientation to the junction at the south pole - this is the analogue of a BPS and anti-BPS junction in the planar Wess-Zumino theory. The action of the global symmetry group can not reverse the orientation of a junction, so they must be considered as different objects, even though they have the same energy density. Thus an n -segment network has only a cyclic C_n symmetry.

A junction in which the phase of the vacuum values increases (upto a 2π periodicity) as each consecutive domain is entered in an anti-clockwise direction will be termed a positive junction, whereas if the phase of the vacuum values continually decreases it will be called a negative junction. Note that for $n > 3$ not all junctions are either positive or negative. With this terminology we can now state that an n -segment network has one positive and one negative junction.

Even in the planar Wess-Zumino model (2.9) a static domain wall network is unstable [15], which is perhaps not surprising given that it must consist of both locally BPS and anti-BPS junctions. Unstable modes are associated with a self-similar shrinking of a domain, which in the thin wall limit (where the width of a domain wall is neglected) become BPS zero modes. It is therefore expected that domain wall networks on the surface of a soliton will also be unstable, and this is indeed the case. The n -segment network is unstable to perturbations which break the cyclic C_n symmetry. For example, if the two junctions are created at points which are not antipodal, or if the segments are not of equal area, then some domains shrink and eventually disappear, leaving the surface dominated by a single vacuum in the generic case.

Let us now turn to the consideration of more complicated networks, with several junctions located at the vertices of a spherical polyhedron and domain walls lying along its edges. To form a given polyhedron (or more accurately its spherical version) an assignment must be made of one of the n vacua to each face of the polyhedron, in such a way that any two faces which meet at an edge have different vacua. This is to ensure that domain walls form along the edges of the polyhedron, but in fact, for reasons that we demonstrate later, a slightly stronger condition must be met, in that no faces which meet at a vertex can share the same vacuum either – basically such a vertex breaks up as domains with the same vacua merge.

By far the most elegant example is the cube in the $n = 3$ theory. To form a cube an allocation must be made of one of the three vacuum values to each of the six faces of the cube, respecting the above criteria that all faces which meet must have different vacua.

This is simple to attain, with each vacuum being assigned twice to opposite faces of the cube. To provide initial conditions for the numerical computations we apply the following general scheme, which works for any polyhedron with a given assignment of vacua to its faces. At the centre of each face we create a sphere of radius R , inside which ϕ takes the required vacuum value j , and outside these spheres we set $\phi = 0$. The only condition on R is that it must be small enough so that no two spheres overlap, and for the simulations described in this paper we set $R = 2$.

Figure 3: Energy density isosurface for the cube network.

In the case of the cube with the assignment described above, the solution computed from the initial conditions is presented in fig. 3, by displaying an energy density isosurface. The energy density is localized on the domain walls, which lie along the edges of a spherical cube, meeting at 3-wall junctions at the cube's vertices. The energy density has octahedral symmetry O_h , the symmetry of a cube/octahedron, because all three species of domain wall have the same tension. Of the eight junctions, four are positive and lie at the vertices of a tetrahedron, whereas four are negative and lie at the vertices of the dual tetrahedron. The configuration is therefore only tetrahedrally symmetric, even though the energy density has octahedral symmetry. In fig. 4 we plot the normalized field $|\phi|/v$ and the magnitude of the Q-ball field $|\psi|$, along the x_3 -axis, for the cube network. This shows how the domain walls are localized around the surface of the Q-ball, where $|\psi| = \frac{1}{\sqrt{2}}$.

As with all the networks we consider, the cube network has negative modes in which the area of any given face shrinks. One way to observe such an unstable mode is to modify the initial conditions so that one of the vacuum spheres placed at a face centre has a radius slightly smaller than the rest. Under the gradient flow evolution this generates a cube network with one slightly smaller square face, which shrinks and eventually disappears, leading to the collapse of the whole network.

The simplicity of the cube network in the $n = 3$ theory might lead to the expectation that almost any polyhedron can be obtained as a domain wall network. However, as we shall see below, the cube network is an exceptional example, being one of the few polyhedra that can be formed.

Figure 4: The functions $|\phi|/v$ (solid curve) and $|\psi|$ (dashed curve) along the x_3 -axis, for the cube network.

To highlight the difficulties in creating a given polyhedron let us discuss another symmetric example, the tetrahedron. Like the cube, the tetrahedron is trivalent, so naively one might think that it could be formed in the $n = 3$ theory, since only 3-wall junctions are required. However, recall that each face of the polyhedron must be assigned a vacuum in such a way that no faces with the same vacuum meet. The four faces of a tetrahedron all meet each other, so this requires at least an $n = 4$ theory. Let us therefore take the $n = 4$ theory and assign a different vacuum to each of the four triangular faces. Recall that the $n = 4$ theory has six species of domain walls, four of which we shall refer to as light walls, and two we call heavy walls, since from the tension formula (2.10) the two heavy walls have a tension which is a factor of $\sqrt{2}$ larger than that of the light walls. The six edges of the tetrahedron are made from four light walls and two heavy walls, since each species of wall occurs precisely once. The two heavy walls are located at opposite edges, and even the energy density is not tetrahedrally symmetric, having only a D_{2d} symmetry. After a short gradient flow evolution the initial conditions yield the almost tetrahedral structure displayed in fig. 5a as an energy density isosurface. Upon further evolution the two heavy walls shrink, as displayed in fig. 5b, and eventually disappear leaving the two antipodal 4-wall junctions presented in fig. 5c. The end point of the evolution is therefore a 4-segment network, rather than the desired tetrahedron network.

As we have explained, the root of the problem lies in the inability to create a network in which even the energy density has tetrahedral symmetry, because walls with different tensions must be used. This obstruction applies to all attempts to create a tetrahedron

Figure 5: Energy density isosurface for an attempted tetrahedral network; a) near the start of the gradient flow evolution, b) midway through the evolution, c) at the end of the evolution.

network for any value of n , and similar problems plague attempts to create almost all polyhedra. For example, the dodecahedron requires the $n = 4$ theory and the four vacua can be assigned symmetrically to three faces each, in a way that covers the twelve faces so that no two meet with the same vacuum. However, each pentagonal face is formed from three light walls and two heavy walls, producing the same kind of problem we have seen for the attempted tetrahedron network.

There are no polyhedral networks which are as elegant as the cube, since walls of different tensions must be employed in all other cases. However, there are a limited number of other polyhedra which can be formed, in a fashion, by arranging the locations of the heavy walls in a particularly symmetric way. The simplest example is an octahedron network in the $n = 4$ theory. A representation of the octahedron is displayed in fig. 6 together with an assignment of one of the four vacua to each face.

Figure 6: A representation of the octahedron together with an assignment of vacua to the faces.

As can be seen from fig. 6, each vacuum is assigned twice to opposite faces of the octahedron. The 4-wall junctions at the north and south poles both contain only light walls, and this accounts for eight of the edges of the octahedron, but the remaining four edges are heavy walls. However, these heavy walls all lie on the equator and have equal length. Although the domain wall junctions lie at the vertices of an octahedron, and the walls lie along the edges of a spherical octahedron, the energy density is only D_{4h} symmetric, because of the different wall tensions. However, this symmetry is enough to allow both light and heavy walls to sit in equilibrium, producing an octahedron network. This is displayed in fig. 7 as an energy density isosurface. It might appear that a variety

Figure 7: Energy density isosurface for the octahedron network.

Figure 8: A representation of the icosahedron together with an assignment of vacua to the faces.

Figure 9: A representation of the pentagonal bipyramid together with an assignment of vacua to the faces.

of polyhedra could be formed in a similar manner as for the octahedron, by a symmetric arrangement of both light and heavy walls. However, it turns out that even very symmetric arrangements often fail to form the intended polyhedron. As an example, consider the icosahedron, which requires the $n = 5$ theory to form the necessary pentamers. There are ten species of walls; five are light and connect vacua whose phases differ by $\pm 2\pi/5$ and the remaining five heavy walls connect vacua with phase differences of $\pm 4\pi/5$. A very symmetric assignment of the five vacua to the twenty faces of the icosahedron is presented in fig. 8. Each vacuum is assigned four times, there are fifteen light walls and fifteen heavy walls, arranged with a cyclic C_5 symmetry. However, even this symmetric arrangement does not form an icosahedron, instead producing a 5-segment network as the end point of the gradient flow evolution.

The mechanism for the collapse of the icosahedron can be understood on a simpler, but related, example. This is the pentagonal bipyramid in the $n = 5$ theory, with the assignment as presented in fig. 9.

As seen in the figure, the five vacua are assigned to the top pentamer in a cyclic order, and to the bottom pentamer in the same cyclic order, when viewed from above. Note that there is a relative rotation of the bottom pentamer through an angle of $4\pi/5$, in order to satisfy the requirement that no two faces containing the same vacuum meet. Clearly a rotation through an angle of $6\pi/5$ would also suffice, and yield a similar configuration. The important observation is that neither of these two alternatives can place the two faces with a given vacuum directly opposite each other, so there is always a preferred direction of rotation in which to untwist the configuration so that faces with the same vacuum can align and unite. It is precisely such an untwisting motion that destroys both the icosahedron and the pentagonal bipyramid.

Fig. 10 displays an energy density isosurface, at two different times during the gradient flow evolution, of the attempted bipyramid associated with fig. 9. Also shown is an isosurface where $\phi \approx v$, indicating where this particular vacuum is attained. The twisting is already clearly visible in fig. 10a, where it can also be seen that 4-wall junctions have split

Figure 10: Energy density isosurface for an attempted pentagonal bipyramid, with the vacuum $\phi = v$ distinguished ; a) near the start of the gradient flow evolution, b) midway through the evolution.

into two 3-wall junctions through the creation of an additional wall. Fig. 10b shows the same configuration after further gradient flow evolution, where the twisting has succeeded in uniting the domains, producing a twisted version of the 5-segment network. Upon further evolution this network untwists and finally forms the 5-segment network. A similar, though more complicated, picture results from the evolution of the icosahedron network.

Figure 11: Energy density isosurface for the hexagonal bipyramid network.

From the above discussion it is clear that even a bipyramid can not be obtained if each of the antipodal junctions contains an odd number of walls. However, in the n -vacua theory, where n is even, a bipyramid with two n -wall junctions can be formed, because the top junction can be rotated by π relative to the bottom junction, placing the same vacua at opposite faces, and thus in unstable equilibrium since there is no preferred direction to begin the untwisting. The simplest example is $n = 4$, in which case the bipyramid is the

octahedron that we have already seen. The next example, $n = 6$, is displayed in fig. 11, where an energy density isosurface is shown to form the hexagonal bipyramid at the end of the gradient flow evolution. The energy density has a D_{6h} symmetry in this example.

4 Archimedean Networks

In the previous section we have seen that a domain wall network requires a consistent assignment of vacua to the faces of a polyhedron and a resulting balance of tensions. This is most easily realized if the network is symmetric, and since we have already discussed the Platonic solids the most natural class to consider next are the Archimedean solids. Rather than compute any examples in detail, we shall apply the criterion that we have outlined in the previous section to determine the Archimedean networks that can be obtained in a theory with three vacua.

The Archimedean solids, of which there are thirteen, are generalizations of the Platonic solids. In an Archimedean solid all vertices are equivalent, but the faces are formed from more than one type of regular polygon. Of the thirteen Archimedean solids it is a simple task to determine that there are three which can be 3-coloured in the way required to be a domain wall network in a theory with three vacua. These three, which are displayed in fig. 12, are the truncated octahedron, the great rhombicuboctahedron and the great rhombicosidodecahedron. The truncated octahedron has 14 faces, of which 6 are squares

Figure 12: The 3-colourable Archimedean solids; a) the truncated octahedron, b) the great rhombicuboctahedron, c) the great rhombicosidodecahedron.

and 8 are hexagons. At each of the 24 vertices one square and two hexagons meet. The three vacua can be assigned by allocating one vacuum to the squares and assigning the remaining two vacua alternately to the four hexagons around each square. The great rhombicuboctahedron contains 12 squares, 8 hexagons and 6 octagons, making a total of 26 faces. At each of the 48 vertices one square, one hexagon and one octagon meet, so an assignment of a different vacuum to each of the three types of polygon can be made. The

great rhombicosidodecahedron has 62 faces, consisting of 30 squares, 20 hexagons and 12 decagons. A square, a hexagon and a decagon meet at each of the 120 vertices, so again each type of polygon can be allocated a different vacuum.

None of these Archimedean solids can arise as domain wall networks in the $n = 3$ model, since all wall tensions are equal, so only a junction with 120° angles exists. However, as discussed in ref.[5] in a general context, it is possible to deform a theory by breaking the $\mathbb{Z}_3$ symmetry so that a junction with specified angles exists. Since all vertices are equivalent in an Archimedean solid, then for each of the three examples described above it is possible to make a (different) symmetry breaking deformation of the potential so that the three wall tensions have the correct ratios to form a junction with the angles required for that particular solid. In the case of the truncated octahedron the deformation breaks the $\mathbb{Z}_3$ symmetry to a $\mathbb{Z}_2$ symmetry, whereas for the other two solids the deformed potential will have no discrete symmetry.

5 Conclusion

Using numerical methods, domain wall networks on the surface of a Q-ball have been studied in a simple model. A small number of polyhedral networks have been found, the cube being the most elegant example, but it has been demonstrated that most polyhedra will not arise because of severe constraints on assigning vacua to faces in such a way that wall tensions are in equilibrium. The analysis presented here reveals that the suggestions of refs.[5, 6] were too optimistic, and one does not expect to find fullerene-like networks of domain walls on the surface of any kind of soliton. This is because our considerations involve only very general arguments, such as the assignment of vacua and wall tensions. The domain wall networks that we have been able to construct should exist in a variety of different theories in which the Q-ball soliton is replaced by a topological soliton, such as a monopole or Skyrmon, with additional fields coupling to the length of the Higgs field or sigma field respectively.

Finally, it is interesting to note that in the $n = 3$ theory the two networks constructed in this paper are examples of Lamarle networks.¹ A Lamarle network is a collection of great circle segments on the sphere which intersect three at a time with 120° angles. There are precisely ten Lamarle networks [13, 12] and it is easy to see that of these ten only two (the 3-segment network and the cube network) can be 3-coloured in the way required to be a domain wall network in a theory with three vacua. Lamarle networks play a role in the study of soap films and bubbles [1], which is another system in which an equilibrium of tensions is required, but only triple junctions are possible in this application [16].

¹I thank Gary Gibbons for pointing this out to me.

Acknowledgements

Many thanks to Dionisio Bazeia and Francisco Brito for helpful correspondence. I acknowledge the EPSRC for an advanced fellowship.
